(57) **ABSTRACT**

Embodiments disclosed herein relate to structural, seismic beams and columns as well as to structures including such beams and columns. The seismic beams and columns may be sized, shaped, or otherwise configured to produce approximately even or uniform load distribution (e.g., during a seismic event and/or wind loading event).

STRUCTURAL MEMBERS AND RELATED METHODS AND SYSTEMS

CROSS-REFERENCE TO RELATED APPLICATIONS

This applications claims priority to U.S. Provisional Application No. 61/888,568 filed on 9 Oct. 2013 and to U.S. Provisional Application No. 61/952,423 filed on 13 Mar. 2014, the disclosures of each of the foregoing applications are incorporated herein, in their entireties, by this reference.

BACKGROUND

Structural systems, (e.g., buildings and similar structures) commonly include interconnected structural members, such as beams and columns. For example, structural beams and columns may form general support and/or frames of a building and may secure one or more building components, such as walls, floors, roof, etc. During a seismic event, the structural members of the building may experience loads that may lead to failure thereof. Furthermore, in some systems, structural fuses may absorb energy imparted onto the structure by the seismic event and may dissipate such energy (e.g., through failure thereof). Failure of such structural fuses, however, may require repair and/or replacement thereof.

Buildings may be configured to resist lateral forces (e.g., from seismic events) by including beams and columns which typically inefficiently absorb the energy imparted into the building by such forces. As such, in some instances, a seismic event may damage the structural members and/or other components of the building. Generally, damaged or failed structural components may require costly repair and/or replacement.

Accordingly, users and manufacturers of structural members and systems continue to seek improvements of such structural members and systems to minimize or eliminate damage thereto from seismic events.

SUMMARY

Embodiments disclosed herein relate to structural, seismic beams and columns as well as to structures including such seismic beams and columns. In some embodiments, the seismic beams and columns may be sized, shaped, or otherwise configured to have an approximately even or uniform stress distribution (e.g., during a seismic event and/or wind loading event). For instance, the seismic beams and/or columns may form or may be included in a moment-resisting frame, which may resist lateral forces. In particularly, the moment-resisting frame may have rigid joints or connections between the seismic beams and columns, such that lateral force applied to the moment-resisting frame produces bending moment and/or shear forces in the seismic beams and columns and/or at joints therebetween.

In at least one embodiment, a seismic beam for fabrication of a moment-resisting frame is disclosed. The seismic beam includes one or more webs extending along a longitudinal axis and a plurality of flanges connected to the one or more webs and extending along the longitudinal axis. At least one flange of the plurality of flanges is positioned on a first side of the one or more webs, and at least another flange of the plurality of flanges is positioned on a second, opposite side of the one or more webs. Each flange of the plurality of flanges has an approximately planar major side that is oriented approximately perpendicular to the one or more webs. Moreover, each major side has a width that gradually decreases along the longitudinal axis from a first location to a second location.

In at least one embodiment, a moment-resisting frame is disclosed. The moment-resisting frame includes a first vertical beam and a second vertical beam oriented approximately parallel to the first vertical beam. The moment-resisting frame also includes a first horizontal beam rigidly connected at a first end thereof to a connection location on the first beam and at a second end thereof to a connection location on the second beam. The first horizontal beam includes a first web having approximately vertical orientation and a first flange connected to the first web. The first flange has an approximately horizontal orientation. The first flange also has a greater width at or near the first end than at an intermediate location between the first end and the second end. The first horizontal beam also includes a second flange connected to the first web and having an approximately horizontal orientation.

Additional or alternative embodiments include a moment-resisting frame that includes a first vertical beam, a second vertical beam, and a first horizontal beam rigidly connected at a first end thereof to a connection location on the first beam and at a second end thereof to a connection location on the second beam. Furthermore, one or more of the first vertical beam, second vertical beam, or the first horizontal beam have a varying moment of inertia that decreases along longitudinal axes thereof from a first location to a second location.

Features from any of the disclosed embodiments may be used in combination with one another, without limitation. In addition, other features and advantages of the present disclosure will become apparent to those of ordinary skill in the art through consideration of the following detailed description and the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

The drawings illustrate several embodiments, wherein identical reference numerals refer to identical or similar elements or features in different views or embodiments shown in the drawings.

FIG. **1** is an isometric view of a seismic beam according to an embodiment;

FIG. **2** is an isometric view of a seismic beam according to another embodiment;

FIG. **3** is an isometric view of a seismic beam according to yet another embodiment;

FIG. **4** is an isometric view of a seismic beam according to still one or more other embodiments;

FIG. **5** is an isometric view of a seismic beam according to yet one other embodiment;

FIG. **6** is an isometric view of a seismic beam according to yet another embodiment;

FIG. **7** is an isometric view of a seismic beam according to still another embodiment;

FIG. **8** is an isometric view of a seismic beam according to at least one other embodiment;

FIG. **9** is an isometric view of a seismic beam according to yet one other embodiment;

FIG. **10** is an isometric view of a seismic beam according to another embodiment;

FIG. **11** is a longitudinal cross-sectional, isometric view of the seismic beam shown in FIG. **9**, with cutouts formed therein according to an embodiment;

FIG. **12** is a longitudinal cross-sectional, isometric view of the seismic beam shown in FIG. **10**, with cutouts formed therein according to an embodiment;

FIG. **13** is an isometric view of a moment resisting frame that includes one or more seismic beams according to an embodiment;

FIG. **14** is a front view of a moment resisting frame that includes one or more seismic beams according to another embodiment; and

FIG. **15** is a front view of a moment resisting frame that includes one or more seismic beams according to yet another embodiment.

DETAILED DESCRIPTION

Embodiments disclosed herein relate to structural, seismic beams and columns as well as to structures including such seismic beams and columns. In some embodiments, the seismic beams and columns may be sized, shaped, or otherwise configured to have an approximately even or uniform stress distribution (e.g., during a seismic and/or wind loading event). For instance, the seismic beams and/or columns may form or may be included in a moment-resisting frame, which resist lateral forces. In particular, the moment-resisting frame may have rigid joints or connections between the seismic beams and columns, such that lateral force applied to the moment-resisting frame produces bending moment and/or shear forces in the seismic beams and columns and/or at joints therebetween.

A typical moment-resisting frame includes conventional beams and columns that have an approximately uniform cross-section along respective lengths thereof. Also, generally, the bending moment experienced by the seismic beams and/or columns, which is produced by application of lateral force to the moment-resisting frame, produces stress in the seismic beams and columns of the moment-resisting frame. In some embodiments, the seismic beams and/or columns described herein may be sized, shaped, or otherwise configured to have an approximately even or uniform distribution of stresses related to bending moments experienced thereby (e.g., along a length or longitudinal axis thereof). Accordingly, to form the moment-resisting frame designed or capable of resisting particular lateral forces, in some embodiments, the seismic beams and/or columns (described below in more detail) may use less material than conventional beams and/or columns.

As described above, the moment-resisting frame may include rigid joints. While the rigid joint may vary from one embodiment to the next, generally, a rigid joint rigidly or substantially inflexibly restrains relative movement (e.g., pivoting) between the beams and/or columns connected at such joints. For example, a rigid joint between a beam and a column may be a welded joint. In some instances, lateral forces applied to the moment-resisting frame may damage or fail one or more rigid joints (e.g., welds) of the moment-resisting frame, thereby compromising integrity thereof as well as integrity of a structure (e.g., a building) reinforced by the moment-resisting frame. In conventional practice, the moment-resisting frame may include preferentially weakened point(s) or location(s) along beams and/or columns (e.g., a Reduced Beam Section (RBS)), which may be near the rigid joints and may allow such beams and/or columns to plastically deform at such preferentially weakened points, thereby reducing the risk of failure at the rigid joints. In some embodiments, distributing the stress along the seismic beams and/or columns of the moment-resisting frame may reduce the risk of joint failure. As such, the moment-resisting frame according to one or more embodiments may include seismic beams and/or columns without preferentially weakened locations that may lead to costly repairs or in irreparable damage after application of lateral forces to the moment-resisting frame (e.g., during a seismic event and/or wind loading event).

FIG. **1** illustrates a seismic beam **100** according to at least one embodiment. The seismic beam **100** may have a generally I-shaped cross-section. For instance, the seismic beam **100** may include a web **110** and flanges **120**, **130** connected to (e.g., attached to or integrated with) the web **110**. The web **110** and the flanges **120**, **130** may extend longitudinally along a longitudinal axis **10** and may define a length of the seismic beam **100**. It should be appreciated that term "seismic beam" is used for ease of description and is not intended to connote a particular orientation (e.g., vertical, horizontal, etc.). Hence, for example, depending on a particular application or structure, the seismic beam **100** may be incorporated as a beam, a column, or any other structural member, which may have horizontal, vertical, or any other suitable orientation.

In some embodiments, the web **110** and/or the flanges **120**, **130** may have approximately planar major surfaces. For instance, the web **110** may have an approximately planar major surface **111**. Similarly, the flange **120** may have an approximately planar major surface **121**. It should be appreciated that the flange **130** may be similar to or the same as the flange **120**. Hence, in some embodiments, the flange **130** may have an approximately planar major surface that may be similar to or the same as the major surface **121** of the flange **120**.

In an embodiment, the major surfaces of the web **110** (e.g., major surface **111** and an opposing major surface) may be approximately perpendicular to one or more major surface of the flange **120** and/or flange **130** (e.g., to the major surface **121**). Accordingly, as described above, in at least one embodiment, the seismic beam **100** may have a generally I-shaped cross-section. It should be appreciated, however, that at least some portions of the major surfaces of the web **110** and/or of any of the flanges **120**, **130** may have non-planar configuration (e.g., irregular, bowed or curved, etc.). Moreover, in some embodiments, the seismic beam **100** may have a generally I-shaped cross-section and generally non-planar major surfaces of one or more of the web **110** and/or one or more of the flanges **120**, **130**.

The cross-sectional area of the seismic beam **100** may change or vary along the longitudinal axis **10**. For example, the cross-sectional area (e.g., taken at cross-section A-A) of the seismic beam **100** may decrease from a first area at or near a first end **101** of the seismic beam **100** to a second area (e.g., taken at cross-section B-B) at or near a second end **102** of the seismic beam **100**. Particularly, the cross-sectional area of the seismic beam **100** at a given location may the sum of the cross-sectional areas of the web **110** and the cross-sectional areas of the flanges **120**, **130** at the given location. Accordingly, the variance (e.g., decrease) of the cross-sectional area of the seismic beam **100** along the longitudinal axis **10** may be produced by varying the cross-sectional areas of one or more of the web **110**, flange **120**, or flange **130** along the longitudinal axis **10**.

For instance, generally reducing the cross-sectional areas of the flange **120** and/or flange **130** along the longitudinal axis **10** may produce reduction of the total cross-sectional area of the seismic beam **100** along the longitudinal axis **10** thereof. In an embodiment, the cross-sectional areas of the flange **120** and/or flange **130** may vary linearly along the longitudinal axis **10**. In some embodiments, the cross-sectional areas of the flange **120** and/or flange **130** may have nonlinear variance along the longitudinal axis **10**. It should be appreciated that varying (e.g., reducing) the cross-sectional area of the seismic beam **100** along the longitudinal axis **10** thereof may result in correspondingly varied (e.g., reduced or increased) moments of inertia (I_x, I_y) of the seismic beam **100** at various locations along the longitudinal axis **10**. Moreover, linear variance of the cross-sectional area of the seismic beam **100** may result in nonlinear variance of one or more moments of inertia (i.e., of the I_x and/or I_y). In some embodiments, nonlinear variance of the cross-sectional area of the seismic beam **100** may result in linear variance of one or more moments of inertia of seismic beam **100**.

In at least one embodiment, the flange **120** and/or flange **130** may be generally tapered, having a greater width at the first end **101** and narrowing toward a smaller width at the second end **102**. For example, the flange **120** and/or flange **130** may have respective base sides **122**, **132** at or near the first end **101** and tapered sides **123**, **133** at or near the second end **102**. In other words, respective widths of the flanges **120**, **130** may progressively or gradually shorten along the longitudinal axis **10** from the first end **101** toward the second end **102** of the seismic beam **100**. In some embodiments, the reduction of the widths of the flange **120** and/or flange **130** along the longitudinal axis **10** may be approximately linear such that the flange **120** and/or flange **130** have generally triangular shapes (e.g., truncated triangular shapes). As such, in some embodiments, the flange **120** and/or flange **130** may have approximately straight or linear longitudinal sides **124**, **125** and **134**, **135**, respectively.

Furthermore, linear reduction in widths of the flange **120** and/or flange **130** may linearly reduce the cross-sectional areas of the seismic beam **100** along the longitudinal axis **10** from the first end **101** toward the second end **102**. Alternatively, the reduction in widths may be nonlinear (e.g., logarithmic, function of a cube root, irregular, etc.), which may produce nonlinear variance (e.g., reduction) of the cross-sectional area of the seismic beam **100** from the first end **101** toward the second end **102**. In some embodiments, the flange **120** and/or flange **130** may have non-linear longitudinal sides (e.g., generally curved or arcuate), which may produce non-linear variance of the respective widths of the flange **120** and flange **130** and cross-sectional areas thereof taken along the longitudinal axis **10**. For example, the non-linear longitudinal sides may follow a generally circular path, a generally elliptical path, or a generally parabolic path. General peripheral shapes of the flange **120** and/or flange **130** (as defined by respective longitudinal sides, base side, and tapered side thereof) may vary from one embodiment to the next. In any event, however, the longitudinal sides of the flange **120** and/or flange **130** may vary in a manner that produces reduction in the respective widths of the flange **120** and/or flange **130** from the first end **101** toward the second end **102** of the seismic beam **100**.

As mentioned above, in some embodiments, the seismic beam **100** may be included in various structures, such as moment-resisting frames. Moreover, in some instances, moments experienced by the seismic beam **100** may vary along the longitudinal axis **10** thereof. In an embodiment, the moments of inertia I_x and/or I_y may generally vary in a similar manner as the moment experienced by the seismic beam **100**. In other words, the moments of inertia I_x and/or I_y of the seismic beam **100** may be sufficient to compensate or counteract corresponding moments along the longitudinal axis **10** may (e.g., in a manner that substantially evenly distributes stress in along the longitudinal axis of the seismic beam **100** and/or avoids, limits, and/or more evenly plastic deformation of the seismic beam **100**).

For example, the moment experienced by the seismic beam **100** during seismic loading may be highest at the first end **101** and lowest at the second end **102**. Hence, the moments of inertia I_x and/or I_y of the seismic beam **100** may be highest at the first end **101** and lowest at the second end **102** of the seismic beam **100** in order to effectively lower and/or more evenly distribute bending stresses caused by the moment. In an embodiment, as described above, the seismic beam **100** may include generally tapered flanges **120**, **130**, such that the moment of inertia I_y of the seismic beam **100** is highest at the first end **101** and lowest at the second end **102**. Accordingly, the seismic beam **100** may have a more efficient or more cost effective distribution material along the longitudinal axis **10** (e.g., as compared with a conventional beam that has approximately constant cross-sectional areas of the flanges and/or of the web along the length thereof).

Generally, the seismic beam **100** may be made from any number of suitable materials. For example, the seismic beam **100** may comprise steel (e.g., rolled steel having tensile strength of about 50 ksi), an aluminum alloy, etc. In some embodiments, the web **110** as well as the flanges **120**, **130** may comprise the same or similar material. Alternatively, as described below in more detail, the web **110**, flange **120**, or flange **130** may comprise materials that are different one from another. In any event, distribution of the material along the longitudinal axis **10** of the seismic beam **100** may be such that more material and/or higher yield strength material is located at locations that are intended to experience higher moment and less material is located at locations that are intended to experience lower moment (e.g., during a seismic event and/or wind loading event).

In some embodiments, the seismic beam **100** may be fabricated from a conventional I-beam or H-beam. For example, portions of the flanges of a conventional beam may be removed or cut away to produce the flanges **120**, **130**. Alternatively, in some embodiments, the flanges **120**, **130** may be welded or otherwise secured to the web **110**.

As described above, the seismic beam may have varying moment of inertia along longitudinal axis or length thereof (e.g., moments of inertia may vary to approximately match anticipated moments experienced thereby). In some embodiments, the seismic beam may experience load or moment having alternating direction along (e.g., along longitudinal axis of the seismic beam), such that a portion or location of the seismic beam experiences no moment thereon. FIG. **2** illustrates seismic beam **100***a* according to an embodiment that may be included in a system or structure where under some loads, the seismic beam **100***a* may experience no moment at or near a center thereof (as measure along longitudinal axis **10***a*). Except as otherwise described herein the seismic beam **100***a* and its elements or components may be similar to or the same as seismic beam **100** (FIG. **1**) and its corresponding elements and components. For instance, the seismic beam **100***a* may include a web **110***a* and opposing flanges **120***a* and **130***a*.

In at least one embodiment, the moment of inertia of the seismic beam **100***a* may alternatingly decrease and increase along the longitudinal axis **10***a*. For example, moment of inertia may decrease from a first location **101***a* on the seismic beam **100***a* to a second location **102***a*, and may increase from the second or intermediate location **102***a* to a third location **103***a* on the seismic beam **100***a*. As such, the seismic beam **100***a* experiencing moment that decreases and increases along the longitudinal axis **10***a* of the seismic beam **100***a*, may proportionally resist such moment. In an embodiment, the second location **102***a* may be approximately midway between the first and second locations **101***a*, **103***a* (e.g., at the center of the seismic beam **100** as measured along the longitudinal axis **10***a*).

As such, in some embodiments, the flange **120***a* and/or the flange **130***a* may have varying cross-sectional shapes along the longitudinal axis **10***a*, which may contribute to varying the moment of inertia of the seismic beam **100***a* in a manner that approximates the moment experienced by the seismic beam **100***a* (e.g., such that the seismic beam **100***a* has a higher moment of inertia at locations experiencing higher moment and lower moment of inertia at locations experiencing lower moment). In at least one embodiment, a cross-sectional area of the flange **120***a* may vary along the longitudinal axis **10***a* such that the cross-sectional area of the flange **120***a* at the first end **101***a* and at the third location **103***a* is greater than at the second location **102***a*. In some embodiments, the second location **102***a* may be located between the first location **101***a* and the third location **103***a* along the longitudinal axis **10***a*.

For instance, the flange **120***a* may have approximately first and second flange portions **121***a*, **122***a*, which may have bases thereof at or near the respective first location **101***a* and second location **102***a*. In some embodiments, the first and second flange portions **121***a*, **122***a* may be connected together or integrated with each other (e.g., without a gap there between). For example, the first flange portion **121***a* and/or the second flange portion **122***a* may be similar to the flange **120** of the seismic beam **100** (FIG. **1**). As such, in at least one embodiment, the first flange portion **121***a* and/or the second flange portion **122***a* may have approximately straight or linear sides. Alternatively, the first flange portion **121***a* and/or the second flange portion **122***a* may have nonlinear sides, as described above in connection with the flange **120** of the seismic beam **100** (FIG. **1**).

In some embodiments, the flange **130***a* may have an approximately the same shape as the flange **120***a*. Alternatively, the flange **130***a* may have a different shape than the flange **120***a* (e.g., approximately uniform shape, a different shape having varying width, etc.). In any event, varying the widths of the flange **120***a* (e.g., of the first flange portion **121***a* and/or the second flange portion **122***a*) and/or of the flange **130***a* or one or more portions thereof may vary the moment of inertia of the seismic beam **100***a* along the longitudinal axis **10***a* in a manner that approximately corresponds to the variance of the moment experienced by the seismic beam **100***a* along the longitudinal axis **10***a*.

As described above, the flanges of the seismic beams may be fabricated by removing a portion of an otherwise rectangular flange. Additionally or alternatively, one or more portions or plates may be attached to an existing or a modified flange of a beam. FIG. **3**, for example, illustrates a seismic beam **100***b* that includes plates **140***b*, **141***b*, **142***b*, **143***b* that may be attached or secured to flanges **120***b*, **130***b*. Except as otherwise described herein the seismic beam **100***b* and its elements or components may be similar to or the same as any of the seismic beams **100**, **100***a* (FIGS. **1**, **2**) and their corresponding elements and components. For instance, the seismic beam **100***b* may include a web **110***b* connected to the flange **120***b* and flange **130***b* and have a generally similar shape to the seismic beam **100** (FIG. **1**).

As mentioned above, the seismic beam **100***b* may be manufactured from steel, aluminum, etc. For example, the web **110***b*, flange **120***b*, and flange **130***b* may be integrated together, while the plates **140***b*, **141***b*, **142***b*, **143***b* may be attached to the respective flanges **120***b* and/or **130***b*. Moreover, in some embodiments, one or more of the plates **140***b*, **141***b*, **142***b*, **143***b* may include different material than the web **110***b*, flange **120***b*, flange **130***b*, or combinations thereof. For instance, the web **110***b* and flanges **120***b*, **130***b* may include material having a first tensile yield strength and the plates **140***b*, **141***b*, **142***b*, **143***b* may include material having a second tensile yield strength, which may be less than or greater than the first tensile strength (e.g., the first tensile yield strength may be 50 ksi and the second tensile yield strength may be 30 ksi, 100 ksi, etc.).

In some embodiments, however, the plates **140***b*, **141***b*, **142***b*, **143***b* may include the same or similar material as the web **110***b* and/or flange **120***b*, **130***b*. Moreover, as described above, fabricating the seismic beam **100***b* may involve removing portions of the rectangular flanges to form the flange **120***b* and/or flange **130***b*. As such, in some instances, removed portions of the original flange(s) may form the plates **140***b*, **141***b*, **142***b*, **143***b*, which may be attached to the flange **120***b* and/or flange **130***b*.

In an embodiment, the plates **140***b*, **141***b*, **142***b*, **143***b* may be smaller than corresponding portions of the flange **120***b* (e.g., portions of the flange **120***b* extending outward from the centerline of the flange **120***b*). Accordingly, in some embodiments, the seismic beam **100***b* may include a gap or space between the plates **140***b*, **141***b* and between the plates **142***b*, **143***b*. Alternatively, however, at least some of the adjacent plates **140***b*, **141***b*, **142***b*, **143***b* may abut one another such that minimizes or substantially eliminate space therebetween. Moreover, in some examples, the in lieu of or in addition to the adjacent plates **140***b*, **141***b* and/or plates **142***b*, **143***b*, the seismic beam may include a single plate that may cover a corresponding portion of or the entire flange **120***b* and/or flange **130***b*, as described below.

FIG. **4** illustrates a seismic beam **100***c* that has varying moment of inertia along the longitudinal axis thereof, according to an embodiment. Except as otherwise described herein the seismic beam **100***c* and its elements or components may be similar to or the same as any of the seismic beams **100**, **100***a*, **100***b* (FIGS. **1-3**) and their corresponding elements and components. For instance, the seismic beam **100***c* may include flange **120***c* and flange **130***c* connected to a web **110***c*, and may generally have generally the same or similar shape as the seismic beam **100***a* (FIG. **2**).

In at least one embodiment, the seismic beam **100***c* may include plates **140***c*, **141***c*, **142***c*, **143***c* attached to the flange **120***c* and/or flange **130***c*. As described above, the plates **140***c*, **141***c*, **142***c*, **143***c* may be formed from the portions removed from flanges of an otherwise rectangular or conventional I-beam or H-beam to form the flange **120***c* and/or flange **130***c*. In some embodiments, each of the plates **140***c*, **141***c*, **142***c*, **143***c* may be continuous or discrete plate that expands from a first end of the seismic beam **100***c* to a second, opposing end thereof. Alternatively, at least some of the plates **140***c*, **141***c*, **142***c*, **143***c* may include multiple (e.g., two or more) portions.

Moreover, as mentioned above, any of the plates **140***c*, **141***c*, **142***c*, **143***c* or portions thereof may include the same material as the web **110**, flange **120**, flange **130**, or combinations thereof (FIG. **1**), or may include material different therefrom. In any event, the plates **140***c*, **141***c*, **142***c*, **143***c* may be attached to the respective flanges **120***c* and/or **130***c* to form the seismic beam **100***c* that has varying moment of inertia along the longitudinal axis thereof. Generally, as described above, the plates **140***c*, **141***c*, **142***c*, **143***c* may be attached to the respective flanges **120***c* and/or **130***c* with any number suitable mechanisms (e.g., fasteners, welding, etc.).

In some embodiments, one or more plates may be attached to a conventional I-beam or H-beam to produce varying moment of inertia along the length or longitudinal axis thereof. FIG. **5** illustrates a seismic beam **100***d* that may include a conventional H-beam **101***d* and plates **140***d*, **141***d*, **142***d*, **143***d*, attached to flanges **120***d*, **130***d* of the conventional H-beam **101***d*, according to an embodiment. Except as otherwise described herein the seismic beam **100***d* and its elements or components may be similar to or the same as any of the seismic beams **100**, **100***a*, **100***b*, **100***c* (FIGS. **1-4**) and their corresponding elements and components. For instance, the seismic beam **100***c* may include the flange **120***c* and flange **130***c* connected together by a web **110***c* and collectively forming the conventional H-beam.

As mentioned above, the seismic beam **100***d* may have varying moment of inertia along the longitudinal axis. More specifically, cross-sectional areas of the plates **140***d*, **141***d*, **142***d*, **143***d* along the longitudinal axis may contribute to the moment of inertia of the seismic beam **100***d* in a manner that the moment of inertia varies along the longitudinal axis to accommodate varying moment experienced by the seismic beam **100***d* at an installation.

It should be appreciated that, generally, the plates **140***d*, **141***d*, **142***d*, **143***d* may be attached to the flange **120***d* and/or flange **130***d* in any suitable manner and with any suitable mechanisms. For instance, the plates **140***d*, **141***d*, **142***d*, **143***d* may be fastened, welded (seam welded, spot welded, brazed, etc.), or otherwise secured to the flange **120***b* and/or flange **130***b*. In an embodiment, at least some of the plates **140***d*, **141***d*, **142***d*, **143***d* may include stich welds **150***d* that may secure the plates **140***d*, **141***d*, **142***d*, **143***d* to the respective flange **120***d* and/or flange **130***d*.

In some embodiments, outer edges of the plates **140***d*, **141***d*, **142***d*, **143***d* may be within a general lateral perimeter for the flange **120***d* and/or flange **130***d*. Alternatively, however, as shown in FIG. **6**, according to an embodiment, a seismic beam **100***e* may include plates **140***e*, **141***e*, **142***e*, **143***e* attached to flange **120***e* and/or flange **130***e*. Except as otherwise described herein the seismic beam **100***e* and its elements or components may be similar to or the same as any of the seismic beams **100**, **100***a*, **100***b*, **100***c*, **100***d* (FIGS. **1-5**) and their corresponding elements and components. For instance, the seismic beam **100***e* may include a web **110***e* connecting together the flange **120***e* and flange **130***e* (e.g., similar to the seismic beam **100***d* (FIG. **5**)). In one or more embodiments, at least some portions of one or more of the plates **140***e*, **141***e*, **142***e*, **143***e* may be wider than the flange **120***e* and/or flange **130***e*. In other words, at least some portions of the plates **140***e*, **141***e*, **142***e*, **143***e* may protrude outward past the perimeter of the flange **120***e* and/or flange **130***e*.

In some embodiments, the seismic beams may include one or more openings or cutouts in the webs thereof. FIG. **7** illustrates a seismic beam **100***f* that include approximately cutouts **160***f* in a web **110***f*, according to an embodiment. For instance, material removed from the web **110***f* (when forming the cutouts **160***f*) may be reused or recycled, thereby reducing material cost of the seismic beam **100***f*. Generally, the cutouts **160***f* may be equidistantly spaced one form another along the longitudinal axis of the seismic beam **100***f*. Alternatively, however, spacing from one to another of the cutouts **160***f* may vary along the seismic beam **100***f*.

In some embodiments, the cutouts **160***f* may be approximately circular. Hence, for instance, the cutouts **160***f* may be machined with one or more rotary tools. In alternative or additional embodiments, as shown in FIG. **8**, a seismic beam **100***g* may include a non-circular cutouts **160***g* in a web **110***g* of the seismic beam **100***g*. It should be appreciated that specific shapes, size, spacing, and number of the cutouts may vary from one embodiment to the next. Moreover, any of the seismic beams **100***a-e* described above may include one or more cutouts in the respective webs thereof, which may be similar to the cutouts **160***f* (FIG. **7**) and/or cutouts **160***g*.

While, as described above, in some embodiments, seismic beams and/or columns may include a single web that secures opposing flanges, in additional or alternative embodiments, seismic beams and/or columns may include multiple webs that secure opposing flanges. FIG. **9** illustrates a seismic beam **100***h* that includes webs **110***h*, **111***h* connecting opposing flanges **120***h*, **130***h*, which may generally have a tubular shape, according to an embodiment. Except as otherwise described herein the seismic beam **100***h* and its elements or components may be similar to or the same as any of the seismic beams **100**, **100***a*, **100***b*, **100***c*, **100***d*, **100***e* (FIGS. **1-6**) and their corresponding elements and components. For example, the moment of inertia of the seismic beam **100***h* may vary from a first end **101***h* toward a second end **102***h* of the seismic beam **100***h* (e.g., the moment of inertia at the second end **102***h* may be smaller than at the first end **101***h*).

In one or more embodiments, the web **110***h*, **111***h* and the flange **120***h*, **130***h* may collectively form or define an opening **170***h*, which may extend longitudinally through the seismic beam **100***h*. For instance, the web **110***h* may be approximately parallel to the web **111***h* and perpendicular to the flange **120***h* and flange **130***h*. Hence, the seismic beam **100***h* may have a generally rectangular or square cross-sectional shape. Likewise, the opening **170***h* may have a generally rectangular cross-sectional shape. It should be appreciated, however, that the seismic beam **100***h* and/or the opening **170***h* may have any suitable shape, which may vary from one embodiment to the next (e.g., triangular, polygonal, circular, or other suitable cross-sectional shape).

Similar to the seismic beam **100** (FIG. **1**), the flange **120***h* and/or the flange **130***h* may contribute continuously smaller amounts of cross-sectional area along the longitudinal axis of the seismic beam **100***h* from the first end **101***h* toward the second end **102***h*. For example, the flange **120***h* and/or flange **130***h* may be tapered (e.g., generally triangular). In additional or alternative embodiments, the seismic beam **100***h* may have any suitable peripheral shape or taper.

While the seismic beam **100***h* includes two webs **110***h* and **111***h* and two flanges **120***h*, **130***h*, it should be appreciated that seismic beams and/or columns may include any number of webs and flanges, which may vary from one embodiment to the next. Hence, as noted above, the cross-sectional shape of the seismic beam and/or column may vary from one embodiment to the next. Moreover, it should be appreciated that any of the seismic beams described above may include multiple webs and/or flanges. For example, FIG. **10** illustrates a seismic beam **100***k* that has an approximately rectangular cross-sectional shape (e.g., similar to the seismic beam **100***h* (FIG. **9**) and has alternatingly varying moment of inertia along longitudinal axis (e.g., similar to the seismic beam **100***a* (FIG. **2**)). Except as otherwise described herein the seismic beam **100***k* and its elements or components may be similar to or the same as any of the seismic beams **100**, **100***a*, **100***b*, **100***c*, **100***d*, **100***e*, **100***h* (FIGS. **1-6**, **9**) and their corresponding elements and components.

The seismic beam **100***k* and the seismic beam **100***h* (FIG. **9**) may be fabricated using any number of suitable manufacturing methods and techniques. For instance, the seismic beam **100***k* may be fabricated by attaching together (e.g., welding) webs **110***k*, **111***k* and flanges **120***k*, **130***k*. Additionally or alternatively, the seismic beam **100***k* may be fabricated by selectively compressing and/or stretching an extruded or folded rectangular tube.

Furthermore, as mentioned above, any of the seismic beams and/or columns described herein may include one or more cutouts in the webs thereof. FIGS. **11-12** illustrate seismic beams seismic beam **100***m*, seismic beam **100***n* with multiple webs, which include multiple openings therein. Except as otherwise described herein the seismic beam **100***m*, seismic beam **100***n* and their elements or components may be similar to or the same as any of the seismic beam **100**, seismic beam **100***a*, seismic beam **100***b*, seismic beam **100***c*, seismic beam **100***d*, seismic beam **100***e*, seismic beam **100***h*, seismic beam **100***k* (FIGS. **1-6**, **9**, **10**) and their corresponding elements and components. FIG. **11** illustrates an a seismic beam **100***m* that includes webs **110***m*, **111***m* with polygonal cutouts **160***m* therethrough, according to at least one embodiment.

In at least one embodiment, the seismic beam **100***m* may include cutouts **160***m* that pass through both webs web **110***m* and **111***m*. In other words, the cutouts **160***m* in the web **110***m* may be aligned with the cutouts **160***m* in the web **111***m*, thereby forming openings through the webs **110***m* and **111***m*. Alternatively, as shown in FIG. **12**, a seismic beam **100***n* may include cutouts **160***n* in a web **110***n* that are offset along the longitudinal axis of the seismic beam **100***n* from cutouts **161***n* in web **111***n*. In other words, the cutouts **160***n* and **161***n* may be at least partially misaligned one from another along the longitudinal axis of the seismic beam **100***n*. It should be appreciated that, in some examples, one or more of the cutouts in the webs may be aligned with one another, while one or more other cutouts may be misaligned one from another.

As mentioned above, the seismic beams described herein may be incorporated into and/or may form any number of structures. Although FIGS. **13-15** are illustrated as utilizing one or more of the seismic beams **100***a* shown in FIG. **2**, any of the seismic beams disclosed herein may be used instead of the seismic beam **100***a*, such as the seismic beam **100***c*-**100***e* shown in FIGS. **4-6**, respectively. Additionally, as used herein including the claims, the terms "horizontal" or variants thereof and "vertical" or variants thereof include deviations from perfectly horizontal or perfectly vertical and are used herein merely for simplicity and convenience.

FIG. **13** illustrates a moment-resisting frame **200** according to an embodiment. For example, the moment-resisting frame **200** may include one or more horizontally oriented seismic beams **100***a* rigidly connected to and between opposing vertical seismic beams **100***a*'. In other words, the moment-resisting frame **200** may include rigid joints between the seismic beams **100***a*' and the seismic beam(s) **100***a*. For instance, the seismic beams **100***a* may be welded to the seismic beams **100***a*' at connection locations therebetween.

Additionally or alternatively, the rigid joints between the seismic beams **100***a* and seismic beams **100***a*' may include bracketed and/or bolted connections. In any event, in at least one embodiment, application of a lateral force F or F' to the moment-resisting frame **200** may produce bending and/or twisting (e.g., elastic or plastic deformation) of the seismic beams **100***a* and/or seismic beams **100***a*', while the joints therebetween may rigidly hold the seismic beams **100***a* and seismic beams **100***a*' together. Moreover, in some embodiments, each of the vertical seismic beams **100***a*' may include a single continuous beam or multiple beams connected together (e.g., welded, fastened together, etc.).

In some embodiments, at the connection locations or joint locations between the seismic beams **100***a*' and the seismic beams **100***a*, the flanges of the seismic beams **100***a*' may have the widest portions. In other words, the seismic beams **100***a*' may have a greatest moment of inertia at the connection locations with the seismic beams **100***a*, and the respective moments of inertia may decrease from the connections locations along the longitudinal axis of the seismic beams **100***a*'. Furthermore, in some embodiments, as described above, moments of inertia of the seismic beams **100***a*' may alternate along the longitudinal axes thereof. For example, the moments of inertia of the seismic beams **100***a*' may decrease along the longitudinal axes thereof from a first connection location to an intermediate location and increase to a second connection location (e.g., with another seismic beam **100***a*) along the respective longitudinal axis.

In some embodiments, the intermediate location may be approximately midway between the first and second connection locations. As mentioned above, the moment of inertia may be varied along the seismic beams in any number of suitable ways. For example, at least one portion of one or more of the flanges may be generally tapered or having widths reducing along the longitudinal axis of the seismic beam. In an embodiment, width of the flanges of the seismic beams **100***a*' may decrease from the first connection location to the intermediate location with distance along the longitudinal axes of the seismic beams **100***a*'. Moreover, the width of the flanges of the seismic beams **100***a*' may increase from the intermediate location to the second connection location. For instance, the widest portion of the flanges of the seismic beams **100***a*' may be located at or near the connection locations or joints with the seismic beams **100***a*.

As mentioned above, in some examples, application of force F and/or F' to the moment-resisting frame **200** may produce an approximately even or balanced distribution of bending stresses along the respective longitudinal axes of the seismic beams **100***a* and/or **100***a*'. In other words, material in the seismic beams **100***a* and/or in the seismic beams **100***a*' may be distributed along respective longitudinal axes thereof in a manner that reduces the total amount of material required or suitable for withstanding the forces F and/or F' as compared to conventional I- or H-beams of approximately uniform cross-section along the longitudinal axes thereof.

In some embodiments, the moment-resisting frame **200** may include two or more seismic beams **100***a*, the may extend horizontally between the seismic beams **100***a*'. It should be appreciated, however, the moment-resisting frames may include any number of seismic beams or columns described herein, which may have any number of suitable orientations. FIG. **14**, for example, illustrates a moment-resisting frame **200***a* that includes numerous horizontally oriented seismic beams **100***a* rigidly connected to and extending between opposing vertical seismic beams **100***a*'. In some instances, the moment-resisting frame **200***a* may include increased the number of horizontal seismic beam **100***a* having decreased sizes (e.g., flange widths and/or web heights), and may maintain resistance to the same forces F and/or F'. Additionally or alternatively, increasing the number of horizontal seismic beams **100***a*, while maintaining sizes thereof may allow the moment-resisting frame **200***a* to withstand greater lateral forces (as compared with a moment-resisting frame having fewer horizontal seismic beams **100***a* of the same size).

Moreover, in some embodiments, the horizontal and vertical seismic beams and/or columns (e.g., seismic beams **100***a* and seismic beams **100***a*') may have alternatingly varying moment of inertia, as described above. In additional or alternative embodiments, however, the moment-resisting frames may have one or more seismic beams and/or columns that have reducing or increasing moments of inertia from a first location to a second location along the longitudinal axes thereon.

FIG. **15** illustrates a moment-resisting frame **200***b* that includes horizontal seismic beam **100***a* rigidly connected to and extending between opposing vertical seismic beam **100***a*'. The moment-resisting frame **200***b* includes vertical seismic beams **100** that may extend between horizontal seismic beams **100***a*. In some instances, the seismic beams **100** may be rigidly connected to the seismic beams **100***a*. Additionally or alternatively, one or more ends of the seismic beams **100** may be pivotally connected to the seismic beams **100***a* (e.g., allowing at least some pivoting about at least one axis). In any event, the seismic beams **100** may allow the moment-resisting frame **200***b* to absorb increased amount of energy or applied lateral force (e.g., during a seismic event and/or wind loading event), as compared with a moment-resisting frame that includes conventional beams and/or columns.

In one or more embodiments, the moment-resisting frame **200***b* may include one or more conventional beams. For example, in lieu of or in addition to the vertically oriented seismic beams **100***a*', the moment-resisting frame **200***b* may include conventional beams. Additionally or alternatively, any of the seismic beams **100***a* may be replaced with one or more conventional horizontal beams. For example, the uppermost and lowermost of the seismic beams **100***a* of the moment-resisting frame **200***b* may be replaced with conventional horizontal beams.

In some embodiments, the seismic beam **100** may have a higher moment of inertia at first ends thereof and lower moment of inertia at second ends thereof (as described above). For example, all first ends of the seismic beams **100** may be connected to the same seismic beam **100***a* and all of the second ends of the seismic beams **100** may be connected to another, opposing seismic beam **100***a*. Alternatively, some of the first ends of the seismic beams **100** may be connected to a first seismic beam **100***a*, while other first ends of the seismic beams **100** may be connected to a second, opposing seismic beam **100***a*. In other words, the orientation of the moment of inertia gradient along respective longitudinal axes of the seismic beams **100** may vary from one seismic beam **100** to another. In some examples, orientation of the moment of inertia gradient along respective longitudinal axes of the seismic beam **100** may alternate from one to another, such that the moment of inertia gradient of adjacent seismic beams **100** is oriented in opposing directions (e.g., upward and downward).

Generally, spacing between seismic beams **100** may vary from one embodiment to the next. Also, in one or more embodiments, the seismic beams **100** may connect opposing horizontal seismic beams **100***a* along a portion of the lengths of the seismic beams **100***a* or along substantially entire lengths thereof. Moreover, in some examples, the moment-resisting frame **200***b* may include upper and lower sections **201***b*, **202***b*. More specifically, the upper section **201***b* may include a first (e.g., top) seismic beam **100***a*, a second (e.g., middle) seismic beam **100***a*, and seismic beams **100** connected therebetween, and the lower section **202***b* may include the second seismic beam **100***a*, the third (e.g., bottom) seismic beam **100***a*, and seismic beams **100** connected therebetween.

In some embodiments, the seismic beams **100** in the upper section **201***b* may be connected along a first portion of the lengths of the seismic beams **100***a*, leaving an opening **210***b* that does not include seismic beams **100**. Moreover, the seismic beams **100** in the lower section **202***b* may be connected along a second portion of the lengths of the seismic beams **100***a*, leaving an opening **211***b* in the lower section **202***b*, which may be geometrically opposite (e.g., a mirrored image) of the opening **210***b* in the upper section **201***b*. In any event, it should be appreciated that a particular pattern, spacing, and number of seismic beams **100** may vary from one embodiment to the next. Also, in some embodiments, the seismic beams **100***a* may be vertically oriented and connected to other seismic beams **100***a*. Furthermore, as mentioned above, any of the seismic beams described herein may be incorporated in any moment-resisting frame.

While various aspects and embodiments have been disclosed herein, other aspects and embodiments are contemplated. The various aspects and embodiments disclosed herein are for purposes of illustration and are not intended to be limiting.

What is claimed is:

1. A beam for fabrication of a moment-resisting frame, the beam comprising:
- one or more webs extending along a longitudinal axis, the one or more webs including a first side and a second, opposite side; and
- a plurality of flanges connected to the one or more webs and extending along the longitudinal axis, at least one flange of the plurality of flanges being positioned on the first side of the one or more webs and at least another flange of the plurality of flanges being positioned on the second, opposite side of the one or more webs, each flange of the plurality of flanges having an approximately planar major side that is oriented approximately perpendicular to the one or more webs, each approximately major side having a width that gradually decreases along the longitudinal axis from a first location to a second location, the width of each approximately major side gradually increases along the longitudinal axis from the second location to a third location, the second location being positioned between the first location and the third location; and
- wherein the one or more webs and the plurality of flanges form a generally tubular shape.

2. A moment-resisting frame, comprising:
- a first vertical beam;
- a second vertical beam; and
- a first horizontal beam rigidly connected at a first end thereof to a first connection location on the first vertical beam and at a second end thereof to a second connection location on the second vertical beam;
- wherein the first vertical beam, second vertical beam, and the first horizontal beam have a varying moment of inertia that decreases along a longitudinal axis thereof from a first location to a second location, the first vertical beam having a highest moment of inertia at the first connection location, and the second vertical beam having a highest moment of inertia at the second connection location.

3. The moment-resisting frame of claim **2** wherein the moment of inertia of at least one of the first vertical beam, second vertical beam, or the first horizontal beam increases along the longitudinal axis from the second location to a third location.

4. A moment-resisting frame, comprising:
- a first vertical beam, including:
  - a first vertical web;
  - a first vertical flange connected to the first vertical web, the first vertical flange having a varying width, the varying width being greatest at a connection location and gradually decreasing along a longitudinal axis of the first vertical beam in a first direction from the connection location to a reduced width location;
  - a second vertical flange connected to the first vertical web;
- a second vertical beam oriented approximately parallel to the first vertical beam;
- a first horizontal beam rigidly connected at a first end thereof to the connection location on the first vertical beam and at a second end thereof to a connection location on the second vertical beam, the first horizontal beam including:
  - a first horizontal web having approximately vertical orientation;

a first horizontal flange connected to the first horizontal web and having an approximately horizontal orientation, the first horizontal flange having a width that is greater at and/or near the first end than at an intermediate location between the first end and the second end; and

a second horizontal flange connected to the first web and having an approximately horizontal orientation.

5. The moment-resisting frame of claim **4** wherein the width of the first horizontal flange near the second end is greater than the width of the first horizontal flange at the intermediate location.

6. The moment-resisting frame of claim **5** wherein the intermediate location is approximately midway between the first end and the second end of the first horizontal beam.

7. The moment-resisting frame of claim **4** wherein the second horizontal flange has a greater width at and/or near the first end than at the intermediate location between the first end and the second end.

8. The moment-resisting frame of claim **5** wherein at least a portion of at least one of the first horizontal flange or the second horizontal flange has a generally tapered shape.

9. The moment-resisting frame of claim **8** wherein at least one of the first horizontal flange or the second horizontal flange has approximately linear sides.

10. The moment-resisting frame of claim **8** wherein at least one of the first horizontal flange or the second horizontal flange has nonlinear sides.

11. The moment-resisting frame of claim **5** wherein the second horizontal flange has a width that is greater at and/or near the second end than the width of the second horizontal flange at the intermediate location.

12. The moment-resisting frame of claim **11** wherein the first horizontal beam includes a second web connecting the first and second horizontal flanges together.

13. The moment-resisting frame of claim **12** wherein the first horizontal beam has a generally tubular shape.

14. The moment-resisting frame of claim **5** wherein the second vertical beam includes:

one or more webs; and

a plurality of flanges connected to the one or more webs, at least one of the at least one flange having a first width at the connection location and a second width at an intermediate location that is spaced apart from the connection location, the second width being smaller than the first width.

15. The moment-resisting frame of claim **14**, further comprising a second horizontal beam rigidly connected at a first end thereof to a second connection location on the first vertical beam and at a second end thereof to a second connection location on the second vertical beam.

16. The moment-resisting frame of claim **4** wherein the width of the first vertical flange of the first vertical beam gradually increases in the first direction from the reduced width location to another location.

17. The moment-resisting frame of claim **4** wherein a first portion of at least one of the first vertical beam or the second vertical beam extends between the connection location and the intermediate location and has a generally tapered shape.

18. The moment-resisting frame of claim **17** wherein a second portion of at least one of the first vertical beam or the second vertical beam extends between the second connection location and the intermediate location and has a generally tapered shape.
